Abstract:

At Fukue Island (32.75°N, 128.68°E), western Japan, we have been conducting long-term observations of NO\textsubscript{2} vertical profiles using MAX-DOAS (Multi-Axis Differential Optical Absorption Spectroscopy), other gases (e.g., O\textsubscript{3} and CO), and aerosols (BC and PM2.5) since 2009. While long-term trends are all negative for PM2.5, black carbon and CO, severe pollution episodes are occasionally encountered even in recent years, particularly for ozone. The observational data during KORUS-AQ period (April-June 2016) and EMeRGe-Asia (March-April 2018) were intensively analyzed. Tropospheric NO\textsubscript{2} vertical column density (TropoNO\textsubscript{2}VCD) as measured with a MAX-DOAS instrument exceeded $10 \times 10^{15}$ molecules cm\textsuperscript{-2} when air mass traveled quickly from Japan and Korea, while O\textsubscript{3} and PM2.5 peaked at different timings when air mass originated from China. During KORUS-AQ, we found close match between the NO\textsubscript{2} mixing ratio (~270 pptv) at ~300 m altitude derived from MAX-DOAS and that of airborne observations from NASA DC-8 which flew just over the site on 10 June 2016. During EMeRGe-Asia, a heavy pollution episode occurred during 24-28 March 2018 covering wide region over Japan; maximum hourly ozone, CO, BC, and PM2.5 levels at Fukue were 97 ppb, 563 ppb, 1.39 μg m\textsuperscript{-3}, and 79 μg
m$^{-3}$, respectively, on 24 March. The ozone level was highest in the recent 10 years for March, but for 6 hours in 2013. We will include observations at other locations, aircraft measurements, and model simulations, to discuss three-dimensional features of such pollution episodes and modeling capabilities.
